Micropropagation of Sumatra Benzoin is potential to provide good-quality seed for future preservation of the forest and improve the incense sap production. The production of *Styrax* plants is currently limited by the availability of seed. This research demonstrated the micropropagation of Sumatra Benzoin (*Styrax benzoin* Dryander), producing good-quality saplings that could be used for obtaining nontimber forest products. Elite mother plant was selected and used as a source of explants. Identification of healthy trees was carried out based on the phenotype criteria, and the selection of a mother plant was performed through information on the quality and quantity production of incense sap. Micropropagation started from callus induction in young leaves followed by subculture to obtain regeneration of shoots and roots. The combination of NAA and BAP in the culture media greatly affected the growth and development of callus, shoots, and roots. The use of 3 mg/L NAA and 3 mg/L BAP rendered the heaviest calli. Shoots were regenerated with 0.5 mg/L NAA and 3.0 mg/L BAP, and the highest growth of roots was obtained by using of 3.0 mg/L NAA without BAP. This research reports the first *in vitro* propagation technique for *Styrax benzoin*. Further research is underway to obtain very good-quality plant saplings to be used for forest conservation and to increase the production of incense sap as a nontimber forest commodity.

## 1. Introduction

Indonesia is a tropical region with big forest areas that are sources of global oxygen. To improve the quality of Indonesian forest is necessary to produce high-value nontimber forest products. Highly productive trees will become an alternative commodity to the farmers around the forest area, as instead of being logged they will protect the forest areas and increase the welfare of the community [1–6]. One of the candidate plants to be preserved is Sumatra Benzoin (*Styrax benzoin* Dryander). Sumatra benzoin is grouped to division Spermatophyte, subdivision Angiospermae, class Dicotyledonae, order Ebenales, family Styracaceae, genus *Styrax*, and species *Styrax benzoin* Dryander. The

benzoin trees grow well in the forest area in North Sumatera and produce a high-quality incense sap, known as frankincense.

The styrax sap contains bioactive compounds that can be used in various purposes such as medical and cosmetics ingredients in modern and traditional medicine [7, 8]. Tapping of incense is the main livelihood for some residents at villages close to the forest area at Kabupaten Pakpak Bharat, North Sumatera Indonesia (Hotdi Berutu 2019: personal communication). The propagation of Sumatra Benzoin plants in Indonesia is generally carried out through seeds that grow naturally in the forest. This strategy makes it difficult to obtain uniform seedlings that produce good-quality incense sap, as some of the trees produce high quantity of gum resin while some other produce low

amount. Besides, it takes around 10 years for naturally growing plants to produce sap. The production of incense sap possibly would lower down in the future if there is no action being carried out to replant the forest with good-quality saplings. These two problems can be overcome through the production of good saplings via micropropagation from high-quality mother plants. Micropropagation is an appropriate choice for the multiplication of plants, since it allows the production of uniform saplings true-to-type to the mother plant in large quantities and at a relatively short time [9–11], but to the best of our knowledge it has not been applied to Sumatra Benzoin. Micropropagation can be done from various types of explants obtained from a mother plant, namely, seeds, young leaves, petioles, stem segments, axillary shoots, apical or axillary meristems, etc. [12–15]. The composition of the culture medium influences the growth development of the plant [16–19]. Therefore, factors like explant source, growth regulators, mineral nutrients, and incubation conditions should be optimized when propagating valuable plants [20–23], and these factors need to be considered in the propagation of Benzoin plants. The purpose of this study is to apply the micropropagation technique to selected Sumatra Benzoin (*Styrax benzoin* Dryander) plants, in an effort to produce good-quality saplings that produce frankincense in large quantities and with the same quality as the mother plant. The saplings are expected to be planted in tropical forests as a strategy to preserve the forest and to improve nontimber forest product. Good-quality saplings are intended to be distributed for plantation of industrial forest and replantation of deforested field in local area at Kabupaten Pakpak Bharat, North Sumatera, Indonesia.

## 2. Materials and Methods

Micropropagation was carried out at Department of Biology, Faculty of Mathematics and Natural Science, Universitas Sumatera Utara, and at the forest area at Kecamatan Sitellu Tali Urang Julu, Kabupaten Pakpak Bharat, North Sumatera, Indonesia. The area is distributed into eight districts (*Kecamatan*) and fifty-three villages (*Desa*). Two villages at Kecamatan Sitellu Tali Urang Julu were chosen, namely, Desa Lae Lange Namuseng and Desa Rumerah, since they bear a virgin forest with the most extensive forest land with a relatively large number of naturally grown Sumatra Benzoin populations.

**2.1. Identification and Selection of Mother Plant Trees.** Exploration for the Sumatra Benzoin trees was carried out at different and random forest locations with the guide of experience farmers. Healthy Benzoin trees were selected based on the verbal information given by the farmers on the quality and quantity production of incense sap accompanied by scientific judgements. The information for the productivity of incense sap was evaluated based on the estimated amount of gum harvested through traditional techniques at a harvest period in a year. The selection of the target plants was done based on the quantity and quality productions of

incense sap in the past three years. Healthy plants that produced a large quantity of sap and good-quality incense sap were marked as potential source of explants for the micropropagation technique. The survey result for Sumatra Benzoin is summarized in Table 1.

Sixty-two mature and productive plants have been identified in the forest area as possible mother plants; twenty-three trees from among these trees produced large quantities of incense sap with very good quality, but only one of the best trees was selected as the source of explants in micropropagation in further research. The selected Sumatra Benzoin plants are about 10 years old, healthy, having dense leaves, fertile, and producing high quantity of incense gum. The average height of healthy plants is about 5–10 meters, with an average stem diameter of 20–40 cm.

**2.2. Preparation of Culture Medium.** The culture medium used in this study was Murashige and Skoog (MS) medium [24] containing of 30 g/L sucrose and complete nutrients of macro, micro, and trace elements, supplemented with the growth regulators  $\alpha$ -naphthaleneacetic acid (NAA) and benzyl amino purine (BAP). After adjusting the pH of the solution to 5.8, the medium was sterilized at 121°C for 20 minutes. The concentration of growth regulators varied by using 0, 1, 2, and 3 mg/L of BAP and NAA, in a two-factorial experiment as shown in Table 2 [25]. The container used was a 50 mL bottle containing 15 mL of media. One explant was planted in each bottle and five replications were made in all experiments.

**2.3. Explant Preparation and Micropropagation Procedures.** Young leaves, shoot tips, and seeds were collected from selected plants. Young leaves and shoots were cleaned and sterilized, and the hard shells of the seeds were peeled to obtain the embryos for further sterilization. For sterilization, the explants were rinsed with a fungicide solution (2 g/L *Dithane*), followed by cleaning with running water. The explants were then cut into pieces (0.5–1.0 cm), washed successively with distilled water and detergent, rinsed in flow water, followed by dipping in ethanol (70%) for 5 minutes, and rinsed with distilled water. They were then dipped in hypochlorite solution (0.8% w/v NaOCl) for 20 minutes and rinsed with sterile water. The explants were inoculated in MS media supplemented with growth regulators of NAA and BAP as described in Table 1. To eliminate fungal and bacterial contamination, the laminar air flow and the room were sterilized using a UV-C lamp ( $\lambda$  280 nm) for 16 hours. The cultures were incubated at  $25 \pm 2^\circ\text{C}$ . The culture environment in the growth room and the flow cabinet was regularly sprayed with 70% alcohol to maintain sterile conditions. Subculturing was carried out to initiate plants from callus. Seven-week-old calli were transferred to culture media containing the same growth regulators levels and the same environmental conditions as in the callus induction procedure. Data collection to measure the size and weight of callus was carried out after seven weeks of incubation. Plant growth and development such as the number of shoots and roots were counted after an incubation time of 12 weeks. The

superiority of plants based on the quantity of production and the quality of the sap determines the selection of the best mother plant. *In vitro* propagation data were callus weight, shoot development, and root growth due to variations in experimental treatments. Data were analyzed statistically using ANOVA followed by Duncan's multiple range analysis ( $P = 0.05$ ) [25].

### 3. Results

**3.1. Micropropagation of Sumatra Benzoin.** The propagation of Sumatra Benzoin was carried out through callus initiation that was subcultured to induce shoots and roots, with the final goal of obtaining plantlets. Young leaf explants, shoots, and seed embryos were taken from the best-quality mother plants. The explants of young leaves that just grew on the branches of the plant produced the highest callus weight with high growth intensity with minimal fungal contamination. The explants from shoots and seed embryos also produced callus. Leaf explants from flowering branches were also used but they did not produce callus and were always contaminated, probably due to having been exposed for a long time to fungi in the forest. Selecting explants from young leaves is a strategy to reduce fungal contamination, especially when using plant material harvested directly from the forest.

Micropropagation of Sumatra Benzoin at the subculture stage is shown in Figure 1. Seven-week-old callus (Figure 1(a)) was subcultured in the medium at various concentrations of growth regulators (Figure 1(b)). Callus regeneration occurred after six weeks, followed by shoot

formation after 12 weeks (Figure 1(c)) and root shoots (plantlets) (Figure 1(d)). The variation in the combination of the concentration of growth regulators affects the intensity of growth and development of the Sumatra Benzoin plant.

**3.2. Optimization of Callus Induction.** The initial stage of Sumatra Benzoin micropropagation was callus induction. The responses of young leaves, shoot tips, and embryos are summarized in Table 3. Leaf explants that had been exposed to the forest environment for a long time only enlarged in the first week then became filled with fungi due to contamination. Young leaves were selected in this study due to their ability to produce aseptic cultures and a relatively high callus growth.

The concentration of growth regulators affected callus growth, which increased when the explants were supplemented with very high concentrations of BAP or NAA and the combination of both (Table 3). When young leaves were used, most of the explants (76.25%) produced callus, although their sizes were variable (Table 4). There were explants (23.75%) which enlarged without callus formation, or did not grow and experienced browning (although the incubation time was extended for a long time), possibly due to the oxidation of polyphenols in the explant cells [26]. The effects of concentration of BAP or NAA on the weight of callus are summarized in Table 4. Callus weight increased with the concentration of growth regulators, and the highest values were obtained in the A<sub>3</sub>B<sub>3</sub> treatment (388 ± 30 mg) supplemented with 3 mg/L NAA and 3 mg/L BAP. Callus weight was significantly increased in the treatment group with increasing concentrations of benzylaminopurine in the media.

**3.3. Plantlet Production.** The production of *Styrax benzoin* Dryander plants was carried out through successive subculturing by using the same concentration of growth regulators as in callus initiation. The growth and development of shoots and roots of *Styrax benzoin* Dryander after 12 weeks is presented in Table 5. The subculture technique was very effective to induce shoots of Sumatra Benzoin, and the number of shoots was strongly influenced by the growth regulators in the media. In comparison, the calli that were

not subcultured were incubated in the media for up to 12 weeks. This procedure produced very large callus that almost covered the entire surface of the explants but did not produce plantlets. The effect of BAP and NAA and their combination onto the growth of plant shoots is summarized

The experiments were conducted with five replicates. Experimental treatments are described in Table 2. \*Data shown are mean of five replicates followed by different letters are significant according to Duncan's multiple range analysis ( $P = 0.05$ ).

NAA did not produce shoots. The combination of BAP and NAA in the media was determinant for shoot induction. Low concentrations of BAP and NAA stimulated the growth of shoots to some extent, whereas the combination of high NAA and BAP concentrations did not induce shoots in some cases. High concentrations of BAP (3 mg/L) stimulated the induction of shoots of *Styrax benzoin* Dryander. However, increasing the concentration of NAA at low BAP concentrations did not increase the number of shoots in the culture.

The concentration of growth regulators greatly affected the number of roots (Table 5). The results showed that the majority of calli produce roots (60.31%). The concentration of BAP and NAA in medium culture influenced the root growth, with the highest levels found in the A<sub>3</sub>B<sub>0</sub> group (average 5.92 ± 0.12 roots).

#### 4. Discussion

A survey has successfully been carried out to identify good-quality *Styrax benzoin* Dryander trees and to select the best mother plant as the source of explants for *in vitro* plant propagation. Information provided by farmers were very relevant in determining the quality of the trees. A total of 23 *Styrax benzoin* Dryander trees were identified as qualified mother plants, and one of the best plants was used as the source of explants in micropropagation technique. The best plant is about 10 years old, stem diameter 30 cm, height 10 m, very dense, the bark is healthy and relatively not moldy, and it has a lot of incense sap production with very good quality.

Micropropagation of Sumatra Benzoin has been carried out by using explants from the best mother plant. *In vitro* propagation of Sumatra Benzoin was carried out in an effort to get the same high-quality plant as the mother plant.

Selection of explants from young leaves in micropropagation has been successful in reducing fungal contamination of culture media [27, 28]. Explants originating from leaves that had long been spilled in the forest environment were very difficult to be freed from fungal contamination although very strict sterilization has been conducted. The strategy of selecting explants from young leaves and shoots that have just grown on mature tree branches and the inside of the seeds of the plant proved to be minimum from fungal contamination; however, explants of young leaves became the choice in this study due to higher response to callus initiation. To the best of our knowledge, there are not reports on the micropropagation of Sumatra Benzoin; therefore, the optimization of growth regulators to obtain optimum conditions for the development of this plant represents an advance in this subject. NAA and BAP concentrations influenced callus production and the regeneration of shoots and roots. The optimal callus production was obtained by using very high concentrations of 3 mg/L NAA and 3 mg/L BAP in the A<sub>3</sub>B<sub>3</sub> group. The growth trend of callus induction found in the propagation of Sumatra Benzoin plants is similar as that previously reported in studies on other woody plants [29, 30].

The strategy plant seedling has been carried out through subculture of the callus. Shoots and roots have been successfully induced at this stage, but no leaves could be induced so far. The highest shoot regeneration was obtained by using a combination of low concentration of 0.5 mg/L NAA with high concentration of 3.0 mg/L BAP in the A<sub>1</sub>B<sub>3</sub> group. Meanwhile, the best condition for producing roots was to use high concentration 3.0 mg/L NAA without BAP in the A<sub>3</sub>B<sub>0</sub> group. These results indicate that the ratio of NAA and BAP concentrations is crucial in inducing Sumatra Benzoin plantlets. BAP functions as an NAA antagonist in root formation, as previously reported [31–34]. This study

provides the first insight into the micropropagation of Benzoin Sumatra, and more research is needed to optimize the combination of growth regulators for leaf induction and the production of whole Sumatran Benzoin plants. Micropropagation of *Styrax benzoin* Dryander is indeed very difficult, but the results obtained at this stage are very promising because they have produced shoots and roots and hope that they will develop into plants. Further research is underway to obtain good-quality and uniform *Styrax benzoin* Dryander saplings for forest conservation purposes and to increase the production of sap as a source of bioactive compounds of high economic value [35, 36].

## 5. Conclusion

This study provides the first insight into the *in vitro* culture of the Sumatran Benzoin tree. Young leaves of mature trees were treated with several combinations of NAA and BAP. The optimal condition for inducing callus was using high concentrations of NAA and BAP (3 mg/L). The highest number of shoots was obtained with a low concentration NAA (0.5 mg/L) and a high concentration of BAP (3.0 mg/L), whereas the addition of 3 mg/L NAA without BAP stimulated rooting. These results demonstrate the feasibility of obtaining shoot and root regeneration of *Styrax benzoin* to a certain extent, although more research is being conducted to achieve leaf development and plant production. The present study demonstrated the potential for success in plant propagation of this species in an effort to obtain good-quality plant saplings that will be used to conserve forests and to increase the production of incense sap as a nontimber forest commodity.
